Care has been taken to confirm the accuracy of information presented in this course. The authors, editors, and the publisher, however, cannot accept any responsibility for errors or omissions or for the consequences from application of the information in this course and make no warranty, expressed or implied, with respect to its contents.

The authors and the publisher have exerted every effort to ensure that drug selections and dosages set forth in this course are in accord with current recommendations and practice at time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package inserts of all drugs for any change in indications of dosage and for added warnings and precautions. This is particularly when the recommended agent is a new and/or infrequently employed drug.

The Risks of Sleeping Pills

Instructions for This Continuing Education Module

Welcome to the Institute for Continuing Education.

The course, test and evaluation form are all conveniently located within this module to keep things easy-to-manage. To use the mail-in or Fax method of taking the test and receiving your credits follow the steps below:

1. Read and understand the material.
2. After reading and studying the lesson, proceed to the test.
3. Take the test. Be sure to completely fill-in the answers. Use a pencil so if mistakes are made they can be neatly erased and corrected.
4. The final part is the lesson evaluation. Please fill out the evaluation as it helps us create a better learning experience for you. Feel free to add any comments you have about our service and any suggestions as to how we can improve. Completion of this form is essential to obtain continuing education credit.
5. Enclose the completed test and evaluation in an envelope and mail to:
   Institute for Continuing Education
   8176 Center Street, Suite A
   La Mesa, CA 91942

6. Alternatively, you can Fax the registration, test and evaluation form to (503) 218-7415. If you decide to Fax the test and evaluation, make sure all your information is darkened. The date on the certificate is the day it is faxed or the date of the postmark.

7. We recommend you return the materials to us via certified or registered mail. This insures against possible loss and provides you with a dated receipt of mailing.

8. Upon successfully passing the test, you will receive your certification in the mail. Certificates are dated the day of the postmark. The test will be processed and the certificates will be mailed out within 24 hours of receipt. Please allow one week for delivery.

9. A passing score is 75%. If your score is below 75%, we will send or fax you another answer form, at no additional charge, so you can retake the exam. READ the material. COMPLETE the test and evaluation form. RETURN the answer sheet and the evaluation form. SEND by certified mail to insure against loss. SAVE your receipt of mailing.

This module explains risks of sleeping pills which you may not have heard about. It also describes better alternatives.

**Learning Objectives**

1. Explain why sleeping pill usage is associated with increased mortality.
2. Identify why sleeping pills are risky and which ones are the riskiest.
3. Describe what are considered good sleep habits and behaviors.

People who take sleeping pills often hope that sleeping pills will increase their sleep enough to make them more energetic in the day, and they may hope that sleeping pills will improve their long-term health. Unfortunately, nothing could be farther from the truth!

Because life and death are often our primary concern, I would like to first discuss the darkest aspect of sleeping pills. I think that taking sleeping pills is like risking suicide. Later, we will discuss how sleeping pills fail to help us in the day.

**SLEEPING PILL USAGE IS ASSOCIATED WITH INCREASED MORTALITY!**

It is now over 26 years that I have been working to assess the risks of sleeping pills. I have learned that sleeping pills are associated with significantly increased mortality.

This means that people who take sleeping pills die sooner than people who do not use sleeping pills.

I first became interested when I saw the work of Dr. E. Cuyler Hammond at the American Cancer Society. He was a leader of the Cancer Prevention Study I (CPSI). Their work had shown that people who reported long sleep had higher mortality, as well as (to a lesser extent) those with very short sleep. To understand further what this might mean, I went to visit The American Cancer Society, starting a collaboration with has extended over all of these years.
In the CPSI (this was the first of two large studies), in 1959-1960, the American Cancer Society asked its volunteers to give health questionnaires to participants whom the volunteers would be able to contact 6 years later. Because Cancer Society volunteers selected relatives and people whom they knew well, these volunteers accomplished the remarkable feat of collecting questionnaires from over one million Americans and then determining six years later (in over 98%) whether the participants had survived. As most people know, the main finding of this study was that people who smoked cigarettes had much higher rates of mortality from lung cancer and heart disease. The study had also asked about many other aspects of people's health which might cause cancer. Included were simple questions about reported insomnia, hours of sleep, and use of sleeping pills.

In 1964, Dr. Hammond had reported that participants in CPSI who said that they slept more than 7 hours or less than 7 hours had higher mortality than those who slept 7 hours. I wondered if this could be related to sleeping pills and worked with Dr. Hammond and Mr. Lawrence Garfinkel at the American Cancer Society to examine which CPSI participants had died after 6 years. We found that 50% more of those who said that they “often” took sleeping pills had died, compared to participants of the same age, sex, and reported health status who “never” took sleeping pills. This increased risk for those who reported taking sleeping pills was not influenced by how long participants reported sleeping. Whether or not participants reported insomnia did not explain the risk. Incidentally, one third of those who said that they often took sleeping pills also said that they never had insomnia, a matter I will discuss below.

We found that reported insomnia did not predict mortality independent of sleep duration. For example, people who reported sleeping 7 hours who said that they frequently had insomnia had similar mortality to people who said that they slept 7 hours and they had no insomnia. A finding in this study (and many others) was that people who complained of insomnia often reported sleeping as long (or longer) than people who reported no insomnia complaint. Similar paradoxes are found when sleep is measured with EEG (brain wave) recordings. Although people who complain of insomnia do sleep a bit less, on average, than people who report no insomnia, insomnia complaints are not closely related to sleeping less than average. In fact, people who sleep more than 8 hours a night report more insomnia than those who say they sleep 7-8 hours.

There were several limitations in the early CPSI study. The questionnaire had not asked the participants whether the “sleeping pills” they took were what we call prescription hypnotics, or whether they might be
The Risks of Sleeping Pills

tranquilizers, antidepressants, or over-the-counter drugs of various kinds. Prescription hypnotics are those drugs which the U.S. Food and Drug Administration has approved for treatment to promote sleep. Because of computer limitations, there was only a very limited way that we could control the comparison of sleeping pill users with nonusers for other health factors which might cause deaths. Finally, by the time our study was published, people had largely switched from the barbiturate prescription sleeping pills (which were well known to cause thousands of overdose deaths each year) to other sleeping pills such as flurazepam (Dalmane), which were thought to be much safer in overdoses.

To re-examine these risks, the American Cancer Society agreed to ask new questions about sleeping pills to participants in a new study, called The Cancer Prevention Study II or CPSII. In 1982, American Cancer Society volunteers gave health questionnaires to 1.1 million new participants, and the survival of these people was ascertained in 1988. Many years were needed for the final data for this huge number of people to be put entered into computers, assembled into computer tapes, and loaned us by the American Cancer Society. Additional years were needed before the new Pentium computers became available to us, so that we could analyze this enormous amount of information. Even a Pentium needed literally months of constant work to complete all the analyses.

In the new study, we again found that people who said that they used sleeping pills had significantly higher mortality. In this study, we had indicated that we were interested mainly in prescription sleeping pills as distinct from tranquillizers or over-the-counter drugs. Because a reported frequency like “often” may be inexact, we had asked participants to estimate the number of sleeping pills which they took each month. When people were matched for age, sex, race, and education, and a total of 32 health risk factors, those who reported taking sleeping pills 30 or more times per month had 25% more mortality than those who said that they took no sleeping pills. However, we did not determine which particular sleeping pills were associated with this risk. The smaller risk of taking sleeping pills just a few times per month was 10-15% increased mortality, compared to those who took no sleeping pills. Sleeping pills appeared unsafe in any amount.

- 25% increased mortality among those taking sleeping pills nightly
- 10-15% increased mortality among those taking sleeping pills occasionally

To provide a perspective on this mortality risk, we noted that the risk of taking sleeping pills 30 or more times per month was not much less than
the risk of smoking one pack of cigarettes a day, when the analyses were done in a similar manner.

If the association of increased mortality with sleeping pills represents sleeping-pill-caused deaths, then usage of sleeping pills may have shortened the lives of the people taking sleeping pills nightly by several years. Note that the “If” in this statement is important. The fact that usage of sleeping pills was associated with deaths does not prove that the sleeping pills were the cause, since possibly other factors (e.g., a painful cancer) might both cause people to die early and to use sleeping pills, without the sleeping pills having any relationship to the mechanism of death.

With the new computers, in CPSII we were able to examine in much more detail than in CPSI whether the risk of using sleeping pills could be explained by other factors. With these methods, we controlled for 32 different questionnaire responses which might have been related to sleeping pill use, for example, whether the participants said they had heart disease or cancer. In these cases, if people used sleeping pills because they had cancer, and it is the cancer (not the sleeping pills) which caused their increased mortality, the control method would remove overestimation of mortality which might not be due to sleeping pills but rather to cancer. On the other hand, if sleeping pills (or cigarettes) cause heart disease which in turn leads to deaths, controlling for heart disease would cause underestimation of the mortality which sleeping pills or cigarettes cause. Even with as much control for other factors as we thought possible in this study, the association of sleeping pill usage with increased mortality could not be explained by chance or by the other factors which we measured. This supports the likelihood that the association is causal.

One cause of death was especially increased. Among men, those who took sleeping pills 30 times a month had 7 times the risk of suicide! Women who took sleeping pills 30 times a month had 2 times the risk of suicide. Nevertheless, the suicides were only a small portion of deaths associated with using sleeping pills. Deaths from other common causes such as heart disease, cancer, and stroke were also increased among sleeping pill users.

To summarize, our new CPSII results in a second million participants confirmed that sleeping pill use is associated with excess mortality. It is probably impossible to design an epidemiologic study which would prove that sleeping pills cause the extra mortality associated with their use. The only way to be certain if the sleeping pills are directly causing the risk would be to randomly offer volunteers either sleeping pills or placebo
The Risks of Sleeping Pills

It is true that such studies would be quite hard to do and expensive, and that ethical concerns would have to be overcome. Nevertheless, people whose loved ones take sleeping pills have an urgent need to know if these pills are safe, which we will not know until random clinical trials are done. Until studies give us more clarity, my best guess is that taking sleeping pills shorten people’s lives by increasing the risk of suicide and other causes of death. This is why I say that taking sleeping pills for a percentage of people may amount to doctor-assisted suicide.

WHY ARE SLEEPING PILLS RISKY, AND WHICH ARE THE RISKIEST?

As a young medical student in my first year of training, one of the first things I learned in our student laboratory was that the kindest way to “put an animal to sleep” permanently was to administer a barbiturate such as pentobarbital. Soon, I learned that when I was a medical student, pentobarbital (Nembutal) was being prescribed almost automatically for patients in the hospital (in a sublethal dose). Use of barbiturates has decreased, but the same drug, pentobarbital (Nembutal) is sold today as a sleeping pill for our relatives and friends. Veterinarians are still using pentobarbital today to put animals to sleep. Related drugs are used to execute the death penalty. Any medical student knows that these drugs can kill.

Doctors have a wonderfully complete understanding of how sleeping pills such as pentobarbital kill animals. These drugs bind with protein molecules called GABA receptors on the surface of nerve cells. The same protein receptor molecules bind at the same time with a neurotransmitter chemical called GABA, which gives them their name. Barbiturates and other sleeping pills accentuate the action of GABA, which is to cause the receptor molecule to allow chloride ions to enter the nerve cells. Since the chloride ions are negatively charged, they make the inside the nerve cell more negatively polarized, which in turn, makes the nerve cells less likely to fire (to generate nerve activity). When the nerve cells which stimulate the muscles of breathing are inhibited from firing action potentials by GABA and by sleeping pills, the animal stops breathing. When breathing stops, the animal dies within a few minutes from lack of oxygen in the lungs. No doubt these same mechanisms explain how barbiturates kill people who take too high a dosage, either accidentally or with suicidal intention.

Barbiturates such as pentobarbital (Nembutal), amobarbital (Amytal), and secobarbital (Seconal) are particularly dangerous in overdose. Indeed,
The Risks of Sleeping Pills

when combined with a modest dose of alcohol--just a couple of drinks--as few as 2 to 3 pills might kill. Other sleeping pills which may have similar overdose risk to the barbiturates may include chloral hydrate (Noctec), methaqualone (Qualude), and ethchlorvynol (Placidyl). Fortunately, usage of these drugs has decreased in the last 30 years, and the number of deaths from sleeping pill overdoses seems to have been reduced correspondingly.

In the 1970’s, a new group of sleeping pills became popular, molecules which chemically are named benzodiazepines. The first sold as tranquilizers were chlordiazepoxide (Librium) and diazepam (Valium). Soon, the benzodiazepine flurazepam (Dalmane) was marketed as a sleeping pill, and flurazepam soon dominated the market. The main advantage of benzodiazepines is that they are much less likely to produce overdose deaths than barbiturates. The lethal dosage may be several hundred pills. It is rather difficult and expensive to purchase hundreds of these benzodiazepine pills, and it is especially difficult to swallow them before falling asleep, so sleeping pill overdose deaths have dropped. We will discuss other benzodiazepines such as temazepam (Restoril), triazolam (Halcion), estazolam (ProSom), and quazepam (Doral) below, along with zolpidem (Ambien), a drug which acts much like a benzodiazepine. All of these drugs seem to have less overdose risk than barbiturates, but it is still possible to die of overdose when as few as 10 of these pills are combined with alcohol or with other drugs. Thus, perhaps a thousand overdose deaths still occur each year in which benzodiazepines may play a role.

Suicide and accidental overdose are probably not the most common ways in which sleeping pills kill, but the other ways are more poorly understood and less well documented. Here are some of the other possible mechanisms.

All of the sleeping pills can cause “hangover,” that is, they not only reduce the action potentials of our brain cells during sleep, but they also reduce brain cell activity during the day. This can make us sleepy, less alert, confused, and weak during the day. We will discuss psychological consequences of this hangover later, but here I mention the impairments of survival. Because several studies show that people who are responsible for automobile accidents are unusually likely to have sleeping pills in their blood, it is thought that hangover may often cause automobile accidents, as well as other fatal accidents. Moreover, falls are much more common among elderly people who are taking hypnotics.

Recently, physicians have become concerned about sleep apnea, a condition where there are pauses of breathing during sleep. Physicians
suspect that sleep apnea can cause deaths during sleep. Not all studies are in agreement, but several studies have found that when a person with sleep apnea takes sleeping pills, there are more pauses in breathing and the pauses last longer, which could be dangerous. For this reason, many experts recommend that people with apnea should not be given sleeping pills. The problem is that our studies show that almost everybody above age 40 has some sleep apnea, and the majority of people over 65 would meet commonly-used criteria for a diagnosis of sleep apnea. Therefore, a large proportion of people taking sleeping pills must be making their apnea worse.

A final concern in regard to mortality is how people care for themselves. Because hypnotics, like tranquilizers, reduce worry about possible threats and risks in our lives, it is possible that the hangover effects of sleeping pills would reduce people’s attentiveness in taking care of themselves in myriad ways.

**Top Sleeping Pills 2012 – Best Sleep Aids**

*Posted in: Articles, How Can I Get Sleep of the Week*

Getting to sleep at night can be very difficult at times, leaving you up for hours in your bed. So what can we do about it? Taking a sleep aid is a great solution for people who deal with insomnia and those who just can’t get to sleep for any given reason. When you consider taking a sleep aid; however, you need to know what works and what is best for your health. Our team at How Can I Get Sleep encourages you to consider taking a natural sleep aid rather than a product recommended by doctors. All-natural sleep aids are more effective and better for your health than regular sleep aids. Unlike natural sleep aids, other sleeping supplements carry high risks of dangerous side effects that you need to watch out for.

Below is a list and of the three best sleeping pills in 2012 that are safe and very effective for getting you to sleep quickly and keeping you sleeping through the night. They include Alteril, OxySleep, and Melatrol.

Alteril is an all-natural sleep aid that helps cure insomnia. Alteril works extremely well because it combines four major ingredients (Tryptophan, Melatonin, Valerian, and Theanine,) that all work differently to get you a better night’s sleep. Melatonin is the most important hormone for your body to get the sleep it needs. Your body produces it when it senses the need for sleep; however, for some people the body does not produce it correctly, which is why you may struggle getting to sleep. Alteril is a great sleep aid that will improve the quality of your sleep while also giving you the feeling of being refreshed when you wake up in the morning.

- Wake up refreshed
- Get to sleep faster
- Improves the quality of your sleep
OxySleep
OxySleep is another all-natural ingredient that gives you a peaceful night’s sleep. This sleep aid is very effective because it also uses Melatonin, which puts your body into a relaxation state of mind. A great benefit to taking OxySleep is that it doesn’t give you that hangover feeling when you wake up the next morning. When you take OxySleep, you won’t have to worry about staying up all night watching infomercials anymore. This sleep supplement will get you to sleep quickly, and will keep you sleeping peacefully throughout the night.

- No side effects
- No more staying up late watching television
- Will wake up feeling refreshed

Melatrol is the ultimate sleep aid that triggers a chemical reaction in your body to give you the best sleep at night. It also contains Melatonin, which helps stimulate the hormones in your body, which are responsible for relaxing your body for the sleep phase. Melatrol, is proven to work, and has a high customer satisfaction rating. With Melatrol you won’t be up all night tossing and turning, you will actually get the sleep you deserve.

Prescription sleeping pills: What's right for you?
Sleeping pills help when stress, travel or other disruptions keep you awake. If you have chronic insomnia, a better approach may be to remove the cause by changing your lifestyle.

By Mayo Clinic staff

If you’re regularly having trouble either falling or staying asleep (insomnia), make an appointment with your doctor. Treatment is available — but it depends on what’s causing your insomnia. Sometimes, an underlying medical or sleep disorder can be found and treated, a much more effective approach than just treating the symptom of insomnia itself.

Behavior changes learned through cognitive behavioral therapy are generally the best treatment for persistent insomnia. However, there are times when prescription sleeping pills may be helpful. Although sleeping pills don’t treat the underlying cause of your sleeping problems, they may help you get some much needed rest.

Today’s prescription sleeping pills don’t carry the same level of risks of dependence and overdoses as sleeping pills of the past. But risks remain — especially for people who have certain medical conditions, including liver or kidney disease. Always talk with your doctor before trying a new treatment for insomnia.
Here's information on some of the most common types of sleeping pills used today.

Types of prescription sleeping pills
Prescription sleeping pills are available to help you fall asleep easier, stay asleep longer — or both. Before prescribing a medication to help you sleep, your doctor will ask you a number of questions to get a clear picture of your sleep patterns. He or she may also order tests to rule out any underlying conditions that may be causing difficulty sleeping.

To reduce the risk of side effects and of becoming reliant on drugs to sleep, your doctor likely will prescribe medications for two to four weeks. If the first medication you take doesn't work after the full prescribed course, call your doctor. You may need to try more than one prescription sleeping pill before finding one that works for you.

Some prescription sleeping pills are available as generic drugs, which are typically less expensive than are brand-name drugs. Ask your doctor whether there is a generic version available of the medication he or she prescribes. Insurance companies may have restrictions on which sleeping pills are covered, and they may require that you try other approaches to your insomnia first.

Sleeping pills that help you fall asleep
The following prescription medications are used mainly to help you fall asleep.

<table>

Psychological effects of sleeping pills.
People say that the side effects of the prescription sleeping pills are the same as their benefits. At night, we want our consciousness impaired (unless we need to get up in the middle of the night), but in the day, such impairments are adverse effects. The problem is that no sleeping pill remains in the blood all night, impairing consciousness, and then suddenly evaporates at the moment of awakening. Most of the marketed prescription hypnotics, when taken at bedtime, will remain in the blood with at least half strength when morning comes. Only a few prescription hypnotics marketed in the U.S. leave the blood fast enough to be largely gone from the blood by morning: these include zolpidem (Ambien), zaleplon (Sonata), and triazolam (Halcion). Even these drugs may be found in the morning blood if they are taken in the middle of the night. Oddly enough, despite the brief half-life (time to be half-dissipated) of zolpidem, zaleplon, and triazolam, there is fragmentary evidence that these short-acting hypnotics might produce impairments lasting after their disappearance from the blood.

As explained above, sleeping pills suppress the action potentials of a wide variety of brain cells. The psychological effects are to make us sleepy, reduce alertness and vigilance, slow reaction times and judgment, and impair aspects of intelligence and memory. Literally hundreds of studies have been done concerning the psychological effects of sleeping pills, both within hours after ingestion and then during the day following taking a sleeping pill at bedtime. To summarize an extremely complex group of studies, all sleeping pills produce immediate impairments of performance. Further, there is extensive evidence that sleeping pills may impair performance and memory on the following day. The problem of daytime impairment is more severe with the longer-acting drugs such as flurazepam (Dalmane) and quazepam (Doral), because the active by-products of these drugs remain in the blood day after day following only a single dose. When one of the long-acting drugs is taken every night, the blood concentrations accumulate day by day, increasing for up to 10-20 days, reaching much higher concentrations than after the initial dose. Therefore, with flurazepam (Dalmane) and quazepam (Doral), and also with diazepam (Valium) and chlordiazepoxide (Librium) when they are taken nightly as sleeping pills, daytime impairment accumulates after consecutive days of use.

Remarkably there is only a smattering of evidence in special conditions that any sleeping pill ever improves daytime performance. Even when it is possible to show that sleeping pills increase sleep (a little) and even though the short-acting drugs are gone by morning, sleeping pills generally do not improve people’s ability to function in their lives. To the contrary, in the great majority of studies, the sleeping pills impair
daytime performance. The few experiments where sleeping pills seemed to produce transient improvements in performance often involved models of jet lag and shift work, not the common problem of the aging person with insomnia. In the hundreds of studies where the pharmaceutical industry has studied hypnotic effects on waking function, the emphasis has been on trying to reduce impairments caused by these products, not on assisting people’s ability to carry on their lives. A person’s hope and belief that a prescription sleeping pill will improve the person’s function on the next day is consistently betrayed. It simply does not work.

To repeat, as a generalization, taking sleeping pills at bedtime impairs how people perform on the following day. Taking sleeping pills usually makes people function worse, not better.

A telling study.
Some years ago, I was privileged to participate with a group of sleep experts from different medical schools in a study sponsored by Hoffmann-La Roche, the makers of Dalmane (flurazepam). Concerned about the impairments of driving and other performance caused by Dalmane, the manufacturer wanted to see if a very-short-acting benzodiazepine would improve performance. The short-acting drug tested was midazolam, which is sold as an hypnotic in Europe, though in the U.S. it is marketed only as a short-acting anesthetic. Many experiments on hypnotic effects on performance had used young healthy volunteers, who had little room for improvement in their sleep. We thought that healthy volunteers might benefit less than insomniacs who really had disturbed sleep. Perhaps the people who benefit most might be a special group. Therefore, we recruited a group of chronic insomniacs who said they had had insomnia and had taken benzodiazepines successfully for an average of over 13 years. Moreover, we selected volunteers in whom we could verify with EEG-sleep recording that their sleep really was disturbed at night, and then we withdrew these people from their sleeping pills for at least 4 weeks. Once withdrawn from whatever they had been taking, they were studied for two baseline nights while receiving a placebo pill. Then, the volunteers were randomly assigned to receive Dalmane, to receive midazolam, or to continue receiving inactive placebo pills.

As expected, these chronic insomniacs slept about 20-27 min. more for the first two days they were given Dalmane or midazolam than when given the placebo. That was not a big improvement. Remarkably, after 9 or 14 days of administration, there was no statistically-reliable
increase at all in the sleep of the volunteers taking Dalmane or midazolam as compared to those receiving placebo. The volunteers had become tolerant to the sleeping pills, which had lost their effect. Part of the reason that the sleeping pills showed no significant benefit after 14 days was that the placebo group had improved. Perhaps regular sleep habits and the belief that they were being helped had produced this improvement, and possibly, placebo patients improved because they had been two weeks longer off the benzodiazepines they had been previously taking, which might have been making them worse. This is an important point, because the fact that a person taking a sleeping pills is sleeping more than at an experimental baseline does not mean that the pill is working, a point confused in many of the most-quoted studies. In any case, after two weeks, the groups receiving Dalmane and midazolam were not significantly improved compared to placebo patients.

The hope that these powerful hypnotics would increase sleep in these chronic insomniacs (for even 2 weeks) was disappointed.

The small increase in sleep which Dalmane and midazolam produced on the first two nights of administration was not sufficient to produce any improvement in performance, which was measured the following mornings with a variety of sophisticated testing methods. Moreover, by 14 days, both drugs were making performance significantly worse. On tests reflecting driving performance, these sleeping pills would have made the patients less safe drivers.

This study yielded a very interesting observation in these chronic insomniacs who for years had believed in sleeping pills. The volunteers themselves said that they thought the research sleeping pill was good and that it was helping them, even when objective tests and at times, their own family observed that the hypnotics were making them worse. Even the group receiving placebo said that placebo was a good sleeping pill which they would like to use again. That is a lesson in the misperception of sleeping pill users. The group receiving either Dalmane or midazolam liked their pill a bit more than the placebo was liked, even although the active drugs were worse for the patients than placebo. These patients were self-deceived about the value of the medication, almost deluded, thinking the medicines made them better when they actually made them worse.

A rather similar study of chronic insomniacs receiving flurazepam (Dalmane) or triazolam (Halcion) also showed that after several weeks of use, the drugs were no better than placebo. This study was interesting because it studied the period of withdrawal after the research drugs were stopped. Even though the volunteers receiving triazolam were no longer
sleeping better than those given placebo at the end of 5 weeks, when the drugs were stopped, those who had received triazolam developed a drug-withdrawal insomnia which made them worse than those who had taken placebo. This study implied that after several weeks of use, people may take sleeping pills not because they continue to benefit in any way, but because their sleep becomes so much worse when they withdraw. It hurts too much to stop. In effect, they have become habituated or addicted to sleeping pills.

Because these two studies were focused on the kinds of people who are actually chronic users of sleeping pills, it was particularly disturbing that the active drugs did not produce long-term benefit (only deleterious effects). It was particularly revealing that the volunteers thought they were benefiting from the drugs (even placebo), when that certainly was not the case.

Testing intermittent use (3 times a week), a recent study showed a similar result with zolpidem (Ambien). After several weeks of use, those taking this sleeping pill were sleeping better when they took the drug but then worse when they skipped it. Overall, after several weeks of use, their sleep was averaging no better than a group taking inactive placebo.

**Disinhibition of punished behaviors and the dark side of tranquilization.**

To understand why people continue taking benzodiazepine hypnotics when experiments show they improve sleep so little and impair performance, it may be helpful to discuss some affects of these drugs on behavior. In experiments where a laboratory rat will receive an unpleasant shock when it presses a lever, an animal given a benzodiazepine will be more likely to press the lever than an animal given placebo. Scientists say that benzodiazepines disinhibit punished behavior, which means that the animals become more likely to hurt themselves or to behave in a way in which they will be hurt. Another way of saying this is that benzodiazepines disinhibit aversive behaviors. There is a human analogy.

In humans, the action of benzodiazepines is to reduce fears of being harmed, which we may call being “tranquilized.” People very much like this feeling of reduced fear, and there is no doubt that many people like how they feel when taking benzodiazepines. The manufacturers could not sell as many as 100,000,000 benzodiazepine prescriptions in the U.S. yearly if people did not like them. Unfortunately, this tranquilization effect includes the risk of reducing a person’s healthy fear of self-destructive actions. For example, a person driving 80 mph down the
highway approaching a curve ought to slow down for the curve, but taking a benzodiazepine might make the driver less likely to slow down. In some studies, benzodiazepines make people more likely to be aggressive. This blunted fear of harmful behaviors or blunted anxiousness to protect oneself may be one way in which sleeping pills shorten people’s lives.

There is another curious twist to this idea. When we consider that benzodiazepines increase people’s tendency to act in a self-harmful way, it is logical that taking harmful sleeping pills may be one of the harmful behaviors which benzodiazepines tend to increase.

**Lollipops, not sleeping pills.**  
The motivations of physicians to give patients sleeping pills have not been studied extensively, but there is some interesting evidence. Physicians routinely explain their medical thinking in their medical records. Even in the medical records of a distinguished teaching hospital, not one of 331 charts of patients receiving sleeping pills had a proper record of why the pill was given Perry, SW et al. Rationale for the use of hypnotic agents in a general hospital. *Ann.Intern.Med.* 1984;100:441-446. It is safe to assume that there often was no good medical justification. It has been the same in the hospitals where I teach. In the hospital, however, the staff motivations are not hard to understand.

Everyone has heard the stories of nurses awakening patients to give them sleeping pills. When I was a medical student, I learned that nurses like to keep their patients quiet for the night. Physicians routinely write sleeping pill orders in the hospital, because they hate for nurses to call at night and wake the doctor up to get a sleeping pill order. As a medical student, I was instructed that if I wanted to sleep at night, I had better routinely prescribe a sleeping pill for every patient. If we train young doctors this way in hospitals, the habits will carry over to outpatient practice.

When I was a child, my pediatrician would give me a lollipop at every visit to compensate for the pain of the injections I was likely to receive. Unfortunately, physicians don’t give lollipops to adult patients. They give sleeping pills instead, when a big lemon sucker might do less harm. Giving sleeping pills is often a gift-giving behavior which is part of the “bedside manner.” When a distinguished group of physicians from our national Institute of Medicine were asked which times they would give a patient a sleeping pill, they said it was when they knew the patient well. The decision had to do with the doctor-patient relationship, not with any particular complaint or medical diagnosis.
The Risks of Sleeping Pills

In the CPSI study, about 1/3 of people who said that they took sleeping pills “often” said that they never had insomnia. Only a small percentage of patients given sleeping pill prescriptions receive any diagnosis related to sleep disorders. Even if we include all diagnoses related to emotional problems and nervousness, most patients given sleeping pills are not given any diagnosis suggesting a genuine medical reason for the prescription. This suggests that gift-giving explains much hypnotic prescribing.

I don’t want to blame the physicians alone. Patients like to receive gifts! They like to feel that they are taking something which might help, even if there is no scientific evidence. In fact, patients often insist that they need sleeping pills, and may become quite irate if a doctor does not want to provide what the patient wants. When I talk to physicians about sleeping pills, they tell me these stories again and again. I am certain that most physicians try to be ethical about sleeping pills, but they also realize that the patient given a sleeping pill is likely to return for a renewal prescription, whereas the patient refused a sleeping pill may look for another doctor. Doctors are fond of their patients and like to keep them. In fee-for-service medicine, it is also quite clear where the doctor’s financial interest lies.

The problem of addiction.
All prescription hypnotics may be physically addicting drugs, and all are sometimes attractive to drug addicts. By addicting, we mean that these drugs have two properties. First, when we take addicting drug such as narcotics or barbiturates, we develop tolerance so that a given dosage has less and less effect or “stops working.” People who develop tolerance are prone to increase their dosage more and more. I frequently see this problem with long-term users of sleeping pills. Second, addicting drugs cause physical withdrawal symptoms when they are stopped abruptly. The withdrawal symptoms of hypnotics such as barbiturates and benzodiazepines are very well known. They include shakiness and tremor, nervousness and anxiety, panic, hyperactivity and increased reflexes, rapid heart rate, and epileptic seizures and death in the most severe cases. In one sense, the withdrawal syndrome with hypnotics can be worse than withdrawal from heroin, because while the heroin addict experiences withdrawal as a terrible anguish, it is rare that addicts do not survive even the most severe heroin withdrawal. Severe withdrawal of sleeping pills can produce death. The risk of seizures and death is probably more severe with withdrawal of barbiturates than with benzodiazepines. On the other hand, zolpidem (Ambien) seems less prone to cause withdrawal symptoms than the barbiturates or benzodiazepines. As compared to heroin, the withdrawal syndrome may
be more lasting with the hypnotics, perhaps more than a month in some cases, though too little controlled experimentation has been done to be really sure.

The addicting properties of hypnotics manifest themselves in several ways. First, triazolam (Halcion) is such a short-acting drug that many people used to take bedtime doses which (for the first hour) were much stronger than the initial dose of a drug such as flurazepam or temazepam. But because triazolam disappears from blood largely with 2-3 hours, some people find themselves in triazolam-withdrawal before morning. As a consequence, people taking triazolam may experience increased early awakening. I suspect that zaleplon (Sonata) may be similar to Halcion in this regard, since it scarcely increases total sleep time. Although zolpidem (Ambien) has been studied less in this regard, its half-life is not much longer than that of triazolam. I have seen some patients taking Ambien who seem to suffer similar early awakening.

Next, by wake-up time, the person taking zaleplon or triazolam or zolpidem will certainly be approaching withdrawal. The result, in at least some patients, may be increased tension and anxiety during the day. Such anxiety symptoms might develop somewhat later in the day with temazepam (Restoril) or estazolam (ProSom), because of the longer half-life. I have seen two patients who developed panic attacks for the first time while taking triazolam. After withdrawing from this sleeping pill, the panic attacks of these patients disappeared.

Almost any patient discontinuing any of the short-acting benzodiazepines might experience some sense of anxiety and some withdrawal insomnia after discontinuation. Doctors argue whether the withdrawal syndrome universally leaves patients worse than they would be without the drug, but I suspect it often does. This makes it very difficult for patients to stop using these drugs once they have become habituated to them, and sometimes very long-term usage results, because the patient finds too much difficulty withdrawing.

If you listen to the drug companies and many experts who receive research grants from drug manufacturers, they would emphasize that most people who take sleeping pills use them for less than 15 doses in a year and do not become habituated. While this is true, it is likewise true that a small percentage do get into the habit of taking one or more hypnotic pills every night. Because these long-term users take so many pills (365 or more per year), it turns out that most of the hypnotic prescriptions sold go to these chronic users. For example, in our CPSII data, 65% of the sleeping pills reported taken in the past month were taken by people reporting that they took at least 30 doses per month, and
The Risks of Sleeping Pills

these patients reported taking sleeping pills for an average of 5 years. It gives quite a different picture of the sleeping pill industry, when we realize that they are profiting primarily from chronic users who have become habituated or physically addicted to these medicines.

About 2/3rds of sleeping pills are taken by people who use them chronically for several years.

Studies of barbiturate addicts showed that while taking huge doses of these sleeping pills, many addicts slept very little. In some cases, after a long and unpleasant withdrawal, the abstinent addict found himself sleeping more than he had been while taking high sleeping pill doses. It seemed that long-term usage of the barbiturates had actually decreased sleep. Whether a similar phenomenon occurs with the benzodiazepines is uncertain, but it is a possibility. Certainly, the CPSII study and similar studies show that people who use sleeping pills often sleep less than people who do not use them, although that relationship does not distinguish which is cause and which effect. It appears that patients who stop chronic sleeping pill use may find that their sleep actually improves. Maybe it becomes a circular process, where people take sleeping pills because of poor sleep, but sleeping pills cause poor sleep. The situation may be similar to that with alcohol, which can be a sleep-inducing drug with a very short half-life. I know of little study of how much alcoholics sleep while they are drinking, but after abstinence, it is clear that abstinent alcoholics sleep very poorly, and they are unable to obtain a normal sleep duration. It appears that in the long run, chronic usage of alcohol damages the sleep system.

One advantage of some over-the-counter sleeping pills is that there is less evidence that they cause habituation and addiction.

Strange sensations of benefit.
Studies of sleeping pill effects on insomniacs show that they often describe a greater improvement in their sleep than EEG recordings measure. Although the hypnotic medication may hasten sleep onset rather little and decrease awakenings only modestly, the patient feels that the benefit is greater. It often appears based on objective recording that insomniacs are mistaken in their estimate of whether the sleeping pills are helping with sleep. An example was the Dalmane-midazolam study, where the insomniacs said that the drug was helping, even when after 14 days, there was no benefit either by EEG measurement or even by their own estimates of how long they had slept.
Another element may be that the sleeping pills simply make insomniacs forget how much they are awake at night. In the past, many of the over-the-counter sleeping pills contained scopolamine, an anticholinergic drug which causes amnesia but has no substantial sleep-inducing effect. Presumably, scopolamine affected the memory of insomnia rather than its actuality. It just helped people forget how poorly they might be sleeping.

It appears that benzodiazepines may make people less aware of their awakenings or less disturbed by them, because the drug may produce a sense of well-being. Indeed, any number of studies have documented that patients like how they feel when they take sleeping pills. To give perspective, let me mention that people also like how they feel when they take heroin. A good feeling does not mean that taking the drug is wise. I am not insensitive to the idea that some dying people at the end of their lives should receive medications to ease their pain when they want them, even if it shortens their lives. Most people who take sleeping pills are a long way from being ready to die. I do not think that relief of distress justifies a drug which may shorten life for most people who take sleeping pills. Regardless of whether or not you agree with assisted suicide, most patients who seek sleeping pills are not ready for this assistance.

Strange symptoms.
There is a kind of strange symptom which possibly occurs more frequently with Halcion than with other hypnotics. After taking a Halcion—sometimes much later in the day—people occasionally feel confused or find that they cannot remember what they just have done. They may have amnesia for hours of their lives. There are also reports of antisocial behaviors which may be triggered by Halcion. A lawyer once asked me to consult with her client in the jail, where he was awaiting trial for having murdered his sister. The lawyer said her client thought that the Halcion he had been taking had caused him to commit this irrational crime. There would be no way of knowing for certain if that was the explanation. Some scientists feel that more problems are reported with Halcion because of media attention which this drug has received, and the mixed reputation which it developed.

Probably occasional episodes of strange, confused and antisocial behaviors occur after use of all sleeping pills. Although we cannot be certain that Halcion is particularly prone to causing problems of this kind, the available evidence is a cause for concern. Among the newer
drugs, a recent report stated that both zolpidem and zaleplon may produce hallucinations.

**GOOD SLEEP HABITS AND ATTITUDES**

The alternative to sleeping pills is to develop good sleep habits and good sleep attitudes. Good sleep habits and attitude are the best approach for a long-term sleep problem, and they produce surprising improvement.

First, remember that you do not need 8 hours of sleep per night. That old idea just is not so. In our studies in San Diego, the average adult is actually asleep only between 6 and 6.5 hours a night. National polls give similar results. Moreover, in the recent Cancer Prevention Study II results, people who slept 6.5 to 7.5 hours lived a bit longer than people who slept 8 hours or more. The shorter sleepers lived longer! Even people who said that they slept as little as 3.5 hours lived longer than those who slept 8 hours or more! Certainly, if you get only 6.5 or 7 hours of sleep a night, you do not have to sleep any more. Incidentally, controlling for other illnesses, age, and so forth, people who said that they had insomnia lived a little longer than those who did not have insomnia! Therefore, do not worry about insomnia!

- People who said that they slept as little as 3.5 hours lived longer than those who slept 8 hours or more.
- People who said that they had insomnia lived a little longer than those who did not have insomnia.

Short sleep is associated with good health as well as long life. Studies show that in the range that most Americans sleep (which is 6, 7, or 8 hours or so), there are few discernable differences between people. This may surprise you, but people who sleep 6 hours seem to be at least as happy as people who sleep 8 hours. Moreover, people who sleep 6 hours get just as much work done and are just as rich as people who sleep 8 hours. There may be some tendency for people with the shortest sleep times (5 or 6 hours) to be outgoing and energetic, whereas people with the longest sleep times (9 or 10 hours) seem to be more introverted, imaginative, or perhaps a bit depressed. Notice the surprise! People who sleep less are less depressed!

Indeed, hospital studies of depressed patients show something very surprising. When depressed patients are kept awake all night (or at least for the second half of the night, e.g., after 2 AM), they actually feel less depressed the following day. The sleep loss actually helps depressed mood. Moreover, after the wake therapy, taking a nap makes depressive symptoms recur. Wake therapy would be a very popular treatment for
depression except for one problem: people with depression who stay up at night do get sleepy, and after they sleep soundly the next night, the low mood relapses. In my little book *Brighten Your Life*, I explain how this relapse can be avoided with bright light. Evidently, although it is true that people who are getting depressed have poor sleep, it is not true that getting more sleep helps depression. Quite the opposite.

For these reasons, depressed people should not struggle to get more sleep.

People may actually improve their moods by getting up a bit earlier.

There is another factor. Spending too long in bed—as you might expect—causes people trouble with falling asleep and makes them more likely to awaken while in bed. Sometimes, the frustration of lying in bed awake adds to the problem, and it builds on itself, getting worse and worse. The more time the person spends in bed trying to get more sleep, the more trouble develops in falling asleep and the more the person awakens in the night. Surprisingly, it seems that spending too long in bed might be a major cause of sleep trouble among both elderly and depressed people. Fortunately, there is an easy solution.

**People who are spending a lot of time in bed lying awake should spend less time in bed.** This means either going to bed later or getting up earlier. Getting up by a regular time seems to be important, so trouble falling asleep should not persuade you to sleep late. The less time you spend in bed, the more sleepy you will be the next evening. Think about it. If you spend less time in bed, you will surely tend to fall asleep more easily and sleep more soundly in the future. Moreover, the less time you spend in bed, the more you will restore the habit of falling asleep quickly after going to bed, and the more you improve the habit of sleeping soundly. Some doctors would recommend that you should not spend more time in bed than you actually sleep. If you think you only sleep 4 hours a night, spend only 4 hours in bed until you are sleeping all 4 hours. Then you can try increasing time-in-bed about 15 min., e.g., to 4 hours and 15 minutes. You can gradually increase your time in bed on a weekly basis until you are no longer sleepy enough to sleep at least 85% of your time in bed. Once you are sleeping only 85%, that is the longest bed time which you should allow yourself.

Most sleep experts also recommend that whatever bedtime you allow yourself, **you should not go to bed if you do not feel sleepy.** Moreover, if you awaken at night and no longer feel sleepy, get out of bed, and do not go back until you are sleepy again and expect to fall asleep. Even after being up during the night, you should get out of bed.
by your regular awakening time, because sleeping late tends to make the problem worse. Getting out of bed when you are not sleepy makes you sleepier the next night and helps maintain good sleep habits.

Almost all of us have stayed up entirely for a night or two, so we know that nothing terrible happens to us. Many of the patients I talk to say that they have slept only a few hours a night for years, and yet they are somehow afraid that losing sleep will hurt them. Probably not. Remember that if anything, the short sleepers tend to live longer and be less depressed. If you are willing to stay out of bed and amuse yourself somewhere else when you are not sleepy, soon you will stop worrying about sleep. If you lose a whole night’s sleep or part of a night, so what? It will not be so bad, as long as you do not worry about it. When you do go to bed (because you are finally sleepy), you will have restored your confidence that you are likely to fall asleep, so the long-term problem resolves.

If you do begin to worry about how a bad night of sleep will affect you the next day, remember that there is no reason to take a sleeping pill. The sleeping pill is likely to make your performance worse the next day, and very unlikely to help.

Experts also advise that you avoid worrying, watching TV (especially those scary late-night movies), reading scary mysteries, and doing other things besides sleep and sex in bed. The idea is not to make a habit of being worried or alerted in bed. If you are a person who worries, select a place to worry (such as a chair in another room), and sit down to worry there. When you are tired of worrying, then go to bed.

Good sleep habits also require avoiding coffee or anything else with caffeine within 6 hours of bedtime. Alcohol is sometimes a cause of sleep trouble, because although it relaxes us at first, it leads to insomnia as soon as the blood alcohol level falls. Drinking early in the evening may cause trouble falling asleep. Drinking at bedtime may cause midsleep awakenings and early awakening.

People say that exercise helps sleep, but I think the benefit is minimal. Probably it is being outdoors in daylight, which is often where people exercise, which is helpful. We have found that people who are outdoors more have fewer sleep problems.

Controlled scientific studies show that adopting good sleep habits and attitudes is extremely effective in solving long-term sleep problems. It is more effective than sleeping pills.
If good sleep habits and good attitudes do not solve your problem, there is a good chance that you are suffering from depression. You should consult your doctor. You might also consult a sleep specialist at a sleep clinic. You might have a problem with your body clock or another sleep disorder which could benefit from specific treatment. For a chronic problem, I do not advise that you ask a doctor for sleeping pills. It is the wrong approach.

THE BENEFITS OF HYPNOTICS

I have written of the dark side of hypnotics and described the alternative treatment of habits and attitudes, because these are the most important points about sleeping pills. I did not describe benefits until this chapter, because in my view, the risks of sleeping pills are really much more important than the benefits.

A laborious and somewhat misplaced effort has occupied sleep laboratories over the years to measure the small amount by which sleeping pills increase sleep. I will not bore you with the details. The effort is misplaced, in the sense that the prescription sleeping pills increase sleep only a little, so that the exact size of the tiny benefit may be trivial. In most sleep laboratory studies, sleeping pills given to insomniacs increase the duration of sleep only 20-40 min. or even less. This is only a small increase, when we consider that many people who sleep only 5 hours do not complain of insomnia, whereas there are people who sleep 9 hours or more who feel their insomnia is severe. As I have mentioned above, although 20 minute increases in sleep may be statistically significant (which means statistically reliable), they are not functionally significant, since sleeping pills usually produce no measurable improvements in daytime performance.

Zaleplon (Sonata) is an especially unfortunate pill. The official information on this drug stated, “a significant difference from placebo on sleep duration was not demonstrated,” which means that zaleplon generally did not help people sleep more than a dummy pill. Does it make sense to take a hypnotic which does not substantially increase nocturnal sleep? Although this drug might help a person fall asleep 10 minutes faster, possibly it makes sleep worse later the same night, so that total sleep time does not significantly improve.

Zaleplon (Sonata) may NOT significantly increase nightly sleep. Whereas most hypnotics increase sleep a few minutes for the first few nights of use, it is unclear how long the benefits last with continuous nightly usage. In our Dalmane-midazolam study, the benefits were gone in less than 7
The Risks of Sleeping Pills

days as compared to placebo, and in the triazolam-flurazepam study, the benefits were gone after 3 weeks as compared to placebo. Unfortunately, the majority of laboratory studies have used placebo baseline recordings as the control, without counterbalancing the order of placebo and hypnotic. The studies where hypnotic and placebo are given in parallel (at the same time to randomly-assigned volunteers) suggest that participation in laboratory experiments (and spontaneous recovery) lead to improvements in sleep. After 2-4 weeks, the improvement seen in a drug-treated group as compared to baseline may be due to the time-related improvement rather than due to drug benefit.

When we go beyond 4 weeks, there are few properly controlled experiments which show that any sleeping pill increases sleep even a little, with the exception of the 8-week study of Morin. Morin’s study, however, showed that behavioral treatment was as effective as temazepam and more lasting in its benefit. When we ask whether hypnotic drugs work when taken nightly for years, there really is no scientifically convincing evidence of efficacy or benefit.

There is no convincing scientific evidence that taking any sleeping pill for years benefits sleep even a little.

Again, I wish to emphasize that in general, hypnotics do not improve daytime function. Patients often seek this benefit, but they do not receive it. Further, although we hear colleagues mention that perhaps a patient will be healthier if the patient sleeps better, certainly the CPSI and CPSII mortality data do not support any belief that sleeping pills are useful in the treatment of medical illnesses or in preserving health.

RECOMMENDATIONS OF EXPERTS

In 1979, a distinguished committee of our national Institute of Medicine considered the risks and benefits of hypnotics. Noting concern with the side effects and risks of sleeping pills balanced by the lack of evidence for long-term benefit, this distinguished committee recommended that hypnotics generally be limited to short-term use. In 1983, a Consensus Conference held by the National Institutes of Health on the treatment of insomnia. This group recommended that sleeping pills be used mainly for up to 3 weeks, not chronically. Another consensus conference was held in 1990 to discuss problems of sleep in aging. Complaints of insomnia are much more common among people above age 60 years, and 40-50% of all sleeping pills are taken in the U.S. by people older than 60. This consensus group also recommended only short-term use of sleeping pills. A new committee of the Institute of Medicine concluded in 1997 that the
data only supported use of Halcion for two weeks. In summary, there is expert consensus that the medical evidence does not support chronic use of sleeping pills.

Experts have repeatedly reached consensus that long-term use of sleeping pills is not advisable.

Considering these assessments of the evidence, the U.S. Food and Drug Administration (FDA) has not approved any prescription hypnotic drug for long-term use. All of these drugs are therefore only recommended by their manufacturers for short-term use, for example, for 10 days or less. The manufacturers must know, however, that most of their sales go to the chronic users who become habituated or addicted. Once a larger number are introduced to sleeping pills, it is the patients who become habituated to these drugs as chronic users who supply most of the profits. The companies merrily collect their profits, seemingly unconcerned that their drugs are being used mainly in ways which are not recommended or approved.

**THE CHOICE OF HYPNOTICS**

Patients and their doctors face a confusing array of prescription hypnotic drugs, with complex choices about which to select. An important limitation of our study of CPSII data is that it did not determine which of the hypnotic drugs have the most risk. Possibly some of these drugs (perhaps the barbiturates) produce the main mortality risk, and the other compounds might possibly be safer. Diazepam seems to be safe in terms of mortality—and different from at least some of the other drugs which are used as sleeping pills. Clearly, the public needs to know if the particular sleeping pills they are given are safe, but this will not be known until new long-term studies are done.

Since the 1979 Institute of Medicine report, most experts have agreed that the risks of barbiturates are greater than that of benzodiazepines and the effectiveness less, if anything. It is clear that the number of doses of barbiturates needed to produce fatal overdose is lower than the doses of
benzodiazepines. Tolerance (loss of effectiveness) is particularly prompt and well-documented with barbiturates, and the risk of physical addiction is familiar to the physicians who used these drugs. Barbiturates suppress rapid eye movement sleep, producing a rebound increase after withdrawal, which may cause nightmares to the patient withdrawing from barbiturates. Another problem is that barbiturates induce special liver enzymes which may severely alter the metabolism of other drugs, producing unpredictable drug interactions. Considering all these aspects, most experts would never choose a barbiturate for a sleeping pill. Drugs such as pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), and phenobarbital are considered obsolete as sleeping pills.

The disadvantages of the barbiturates are probably shared, to some extent, by methyprylon (Noludar), chloral hydrate (Noctec), Qualude (methaqualone), and glutethimide (Doriden), although the properties of some of these drugs as hypnotics are less fully understood. Some of them are no longer sold on the U.S. market because of the unfavorable balance of risks and benefits. Ethchlorvynol (Placidyl), the drug to which Supreme Court Chief Justice Rehnquist was addicted, is an especially undesirable choice, because sleep laboratory studies have unable to demonstrate that this drug increases sleep to any extent at all. Ethchlorvynol may have risks without any balancing benefits.

The benzodiazepine drugs which came into use in the 1960’s and 1970’s were regarded as a marked improvement, because their overdose risk is low, except when combined with alcohol or other drugs. Also, they are at least as effective as other hypnotics. Their tendency to produce tolerance, addiction, and withdrawal syndromes is usually not severe, and they suppress REM sleep only a little. Benzodiazepines are responsible for few metabolic drug interactions in the liver. There are situations today when a benzodiazepine may be the best available choice.

Two benzodiazepines, flurazepam (Dalmane) and quazepam (Doral) are rapidly metabolized by the body to desmethylflurazepam, which is an active sleep-inducing compound. The half-life (time to be half-eliminated) for desmethylflurazepam in young adults is 3-4 days. In aging people, the half-life of desmethylflurazepam may be even a week or longer. Therefore, with dosage night after night, the blood concentrations of desmethylflurazepam increase day by day to concentrations as much as 5 times or more the concentration on the initial night of use. As a result, people who take flurazepam or quazepam sleep somewhat better on the first night, but they may actually have somewhat more hypnotic effect on the second night, as the metabolite accumulates. Likewise, they are measurably sedated during the first day, and the daytime sedation may increase with nightly use. Fortunately, there seems to be tolerance to the daytime effects, so that as
The Risks of Sleeping Pills

desmethylflurazepam concentrations increase, the daytime sedation may not be severe. However, repeated use of flurazepam and quazepam may produce insidious personality changes with nightly use, especially in elderly patients. In aging patients, the drug may accumulate for several weeks, sometimes leading to confusion or loss of memory, and it may be several weeks after the drug is withdrawn that the personality recovers. These long-acting drugs may also cause the worst problems with daytime weakness, falls, and automobile accidents. On the other hand, because they are self-tapering, these drugs have minimal withdrawal symptoms.

Among aging people, sleeping pills such as flurazepam and quazepam can produce gradually-developing weakness, confusion, and memory loss. Diazepam also has this danger.

Diazepam (Valium) is marketed as a tranquilizer and anticonvulsant, but many physicians prescribe diazepam as a sleeping pill. Diazepam is a relatively short-acting drug on the first night, because its metabolite desmethyldiazepam rapidly enters fat stores. After several days of usage, however, the concentrations of desmethyldiazepam may accumulate, producing accumulating daytime sedation and hangover. Thus, diazepam functions as a moderately-long-acting hypnotic with repeated use. When taken by elderly people, diazepam may accumulate for weeks and produce progressive confusion, memory loss, and weakness. Diazepam is one of the few benzodiazepines where controlled studies have demonstrated long-term effectiveness, albeit as an anti-anxiety agent and not as an hypnotic. In our CPSII analysis, people who said they took "Valium" 30 times or more per month had no increase in mortality risk, unlike those reporting regular "sleeping pill" use. This would be one argument for choosing diazepam.

Temazepam and estazolam have intermediate half-lives, which result in continuing effectiveness throughout the night and diminishing sedation during the day. They do not accumulate significantly with nightly use, at least, until aging increases the half-life. A problem with temazepam in formulations which have been sold in the U.S. is rather slow absorption, so that it is ineffective for decreasing time-to-fall-asleep unless it is taken 30-45 minutes before bedtime. Lorazepam (Ativan) and oxazepam (Serax) have many of the same disadvantages and advantages of temazepam, although they are not marketed specifically as sleeping pills.

Triazolam (Halcion), as mentioned, has a particularly short half-life, so it causes relatively little daytime hang-over. Triazolam is quite effective for helping people fall asleep, but as mentioned, for some patients it produces early awakening. Triazolam may also increase daytime anxiety, tension, and panic. Triazolam produces particularly brisk withdrawal
symptoms. Triazolam might be particularly prone to produce behavioral and memory abnormalities. Because of these side effects, many physicians have largely abandoned triazolam. I cannot imagine a patient for whom I would recommend triazolam.

I would never recommend zaleplon (Sonata), since it does not significantly increase sleep.

Incidentally, most experts would not recommend over-the-counter sleeping pills, although less is known about their effects. The suspicion is that the over-the-counter pills might be safer (at least in terms of addiction) but also even less effective. Most of the comments in this booklet refer to the prescription sleeping pills.

Zolpidem
The final option in the U.S. recently has been zolpidem (Ambien), which rapidly captured the majority of the U.S. market. Although zolpidem is not a benzodiazepine, it binds with benzodiazepine receptors and apparently acts like a benzodiazepine. However, zolpidem binds more specifically to some of the several kinds of benzodiazepine receptors, and for this reason, it possibly causes less muscle weakness and less anti-epileptic effect than most benzodiazepines. It has been claimed that zolpidem distorts EEG sleep patterns less than other hypnotics and that it produces less withdrawal symptomatology. Because of its short half-life, zolpidem produces relatively little hangover but may lack effectiveness for early treating awakening. Zolpidem might increase daytime anxiety in some patients. It appears that zolpidem has little tendency to produce addiction, but addiction with zolpidem does occur. Zolpidem is extremely expensive compared to most hypnotics, and it is not recommended for long-term use. Weighing all factors, many physicians have concluded that zolpidem is the best available choice as a hypnotic for short-term use when early awakening and cost are not problems. I am inclined to agree.

A word about melatonin.
Melatonin was first discovered because it blanches the skin of frogs. Next it was learned that in small animals, melatonin can make the gonads atrophy. Indeed, there is evidence that melatonin interferes with gonadal functions in humans, so it is probably risky for sex and fertility. In some mammals, melatonin whitens the fur or promotes obesity. Considerable evidence indicates that melatonin might cause depression. Melatonin causes headache and nightmares. In animals, melatonin constricts brain blood vessels and affects the arteries of the heart. In humans, melatonin
The Risks of Sleeping Pills

affects blood pressure. Melatonin is a hormone of darkness. I sometimes imagine that melatonin is recommended by the same sorcerers of darkness who mix owl eyes, newt ears, and wormwood to make magical concoctions. You might wonder why people think melatonin is such a great idea. So do I.

It has been claimed that melatonin is low among people with insomnia. Don’t believe it. In our studies, there appears to be little or no relationship.

It has been claimed that melatonin is useful for treatment of insomnia. In most studies, the sleep benefit is very weak or completely absent. Melatonin is not a hypnotic drug. For example, in rats, melatonin is highest when the animals are most alert. For the person whose sleep problem is awakening during the night or awakening too early in the morning, there is evidence that melatonin would do more harm than good.

Melatonin does have some effects on the body clock. There are some studies which suggest that melatonin helps with jet lag or night shift problems, and other studies which show no value in these situations. There has been insufficient testing. In my opinion, about the only application where benefits of melatonin seem quite likely to outweigh risks is for the completely blind person who may have lost his or her eyeballs.

You may have guessed that I do not recommend melatonin. I do not.

HOW MUCH ARE SLEEPING PILLS USED IN THE UNITED STATES?

I do not think anybody has reliable information on how much Americans take sleeping pills. Most scientific discussion cites data from the National Prescription Audit, a survey system conducted by IMS America, Ltd. Their survey methods are proprietary, and I do not know in detail what they are, but they involve computerized monitoring of retail pharmacy sales. For the year 1995, the National Prescription Audit provided me information on sleeping pill sales, which totaled 18 million new and refill proscriptions with an estimated total retail cost of close to $1 billion. Zolpidem (Ambien) at that time had less than one half the U.S. sleeping pill prescriptions, but because of its high cost, zolpidem received most of the dollar sales. After that time, zolpidem increased its market share, but currently it has new competition. Nevertheless, I am skeptical that the
National Prescription Audit reports all of the sleeping pills which Americans take.

First, although the National Prescription Audit includes certain mail-order pharmacies and drugs distributed to private nursing homes as well as retail pharmacies, it does not monitor all medications distributed by health maintenance organizations, hospitals, or public clinics such as community mental health centers. Obviously, HMO’s are becoming a growing part of the medical market. Also, it does not include drugs distributed by the Department of Veterans Affairs or Public Health Service and military hospitals, which provide a substantial portion of America’s medical care. National hypnotic consumption figures based on the National Prescription Audit simply ignore numerous avenues of distribution.

This lack of monitoring might seem surprising, considering that the sleeping pills are addicting drugs governed by the narcotics laws, and everybody knows that they are occasionally drugs of abuse. Recently temazepam became popular among drug abusers in England. Rohypnol, the “date rape” benzodiazepine not sold legally in the United States, has obviously become widely available. Pharmacologically, Rohypnol is not distinct from other marketed benzodiazepine hypnotics. Who knows why drug abusers prefer “reds” (Seconal?) one year and Rohypnol another? In any case, the federal ostrich has its head in the sand.

Consider that the National Prescription Audit reported under 100,000 prescriptions of pentobarbital (Nembutal) totaling about 2,000,000 doses, but the government permits the manufacturer to make over 15 tons yearly, enough for seven or eight times as many doses. A cooperative DEA official told me that he thought that the limit was manufactured. Abbott, the manufacturer, refused to tell me what proportion of their sales go to the injectable pentobarbital preparation, which includes both hospital and veterinary markets. Is it possible that a substantial proportion of pentobarbital sales are diverted into illegal channels?

Even given the likely underestimations of the National Prescription Audit data, I believe that the popular estimates of the percentage of Americans who use hypnotics must be incorrect. Consider, the National Prescription Audit reported 37,000,000 yearly prescriptions for hypnotics in 1970, with an average of about 40 pills per prescription, a total of perhaps 1,480,000,000 hypnotic pills. Yet the 37,000,000 prescriptions would have been be sufficient to provide about 4,000,000 Americans with one pill per day, or 99,000,000 Americans could receive 15 pills per year. Yet, at that time, NIH scientists were estimating that only 3.5% of American adults were using any hypnotic pills per year. Something is
terribly inconsistent about those survey estimates. In France and Germany, a much higher percentage of the population is said to take hypnotics, for the most part chronically. I wonder if the American figures aren’t really closer to the European figures than our scientists have realized.

At some personal expense, I filed Freedom of Information requests, asking the FDA, the Drug Enforcement Administration, and Customs what the sales of hypnotics were in the United States. Under penalty of law, the government agencies stalled, but once threatened with legal action, these government agencies stated that they did not have the information. I believe it. I believe that the U.S. government does not know how many sleeping pills Americans use and what percentage of Americans use them. Considering that the hypnotics are addicting drugs and drugs of abuse, I think our government ought to pay better attention.

WHY HAVEN’T YOU HEARD THIS OPINION OF SLEEPING PILLS FROM EVERY EXPERT?

“The treatment of insomnia by drugs is always to be avoided as much as possible.”

- H.C. Woods, 1893

The idea that sleeping pills have a dark side is nothing new. Indeed, generations of physicians have shared my opinion, based on their own clinical experiences. Probably, the majority today agree. They are a silent majority, with little to be gained by making their opinions public.

The sleeping pills industry has a billion dollars of yearly sales, and it has thought of many subtle ways of keeping its products popular. To be frank, the manufacturers of sleeping pills have often given the leaders of sleep research large monetary grants to test their products. These colleagues are very nice people who are not the sort to bite the hand which feeds them. Some of the most prominent leaders of sleep research have been supported mainly by drug company grants. The drug companies have used many subtle free offers and not-so-subtle methods of influencing the wider group of sleep clinicians to mute their critical attitude towards sleeping pills.

For example, a few years ago, manufacturers offered free chocolate cream pie at a national sleep meeting for attendees to watch a bizarre comic session in which leaders of the sleep community mocked the Food and Drug Administration for its efforts to regulate sleeping pills.
suppose a good deal of money was spent for those free chocolate cream pies and the advertising of that clowning.

For several years, the National Sleep Foundation has launched a yearly publicity campaign about the dangers of insomnia, encouraging everybody to sleep 8 hours. Scientific evidence to support 8 hours sleep is almost nonexistent: for example, people live longer who sleep less (see above). Could this campaign be influenced by the fact that much of its money comes from sleeping pill manufacturers? The public relations firm for Ambien bragged that National Sleep Foundation publicity was effective in increasing sleeping pill sales.

Unfortunately, nobody advertises for behavioral treatments, or for hypnotic abstinence. The advertising for light treatment is minuscule compared to pharmaceutical advertising.

Record Sales of Sleeping Pills Are Causing Worries

By STEPHANIE SAUL

Americans are taking sleeping pills like never before, fueled by frenetic workdays that do not go gently into a great night’s sleep, and lulled by a surge of consumer advertising that promises safe slumber with minimal side effects.

About 42 million sleeping pill prescriptions were filled last year, according to the research company IMS Health, up nearly 60 percent since 2000.

But some experts worry that the drugs are being oversubscribed without enough regard to known, if rare, side effects or the implications of long-term use. And they fear doctors may be ignoring other conditions, like depression, that might be the cause of sleeplessness.

Although the newer drugs are not believed to carry the same risk of dependence as older ones like barbiturates, some researchers have reported what is called the “next day” effect, a continued sleepiness hours after awakening from a drug-induced slumber.
Ten percent of Americans report that they regularly struggle to fall asleep or to stay asleep throughout the night. And more and more are turning to a new generation of sleep aids like Ambien, the best seller, and its competitor, Lunesta. Experts acknowledge that insomnia has become a cultural benchmark — a side effect of an overworked, overwrought society.

“Clearly, there’s a significant increase in people who report insomnia and, from my perspective, that is the result of our modern-day lifestyle,” said Dr. Gregg D. Jacobs, a psychologist and assistant professor of psychiatry at Harvard. Or at least that is an impression that drug makers are clearly trying to capitalize on, he said.

And that concerns him and some other researchers who warn that despite their advertised safety, the new generation of sleep aids can sometimes cause strange side effects.

The reported problems include sleepwalking and short-term amnesia. Steven Wells, a lawyer in Buffalo, said he started using Ambien last year because his racing mind kept him awake at night. But he quit after only one month, concerned about several episodes in which he woke up to find he had messily raided the refrigerator and, finally, an incident in which he tore a towel rack out of a wall.

“The weird thing was that I had no recollection of it the next day,” said Mr. Wells, who added that he found the episodes frightening.

Ambien’s maker, Sanofi-Aventis, said the drug had been used for 12 billion nights of patient therapy. “When Ambien is taken as prescribed, it’s a safe and effective treatment,” said Emmy Tsui, a company spokeswoman.

A Food and Drug Administration spokeswoman, Susan Cruzan, said she was not aware of an unusual number of complaints with the drugs.

Drug makers spent $298 million in the first 11 months of 2005 to convince consumers that the sleep aids are safe and effective. That was more than four times such ad spending in all of 2004.

In the last year, much of the advertising surge has been a result of competition from Lunesta, which the drug maker Sepracor introduced last April to compete with Ambien. Through November, Sepracor led the sleeping pill advertising field, spending more than $185 million, according to figures from TNS Media Intelligence, which did not have final figures for December.
In response, Sanofi-Aventis, marketing both Ambien and its controlled-release version, Ambien CR, spent $107 million from last January through November, according to TNS. That was nearly double its ad spending on Ambien in 2004.

Even the most infrequent television viewers would have trouble missing the Lunesta ads, which feature a luna moth fluttering around the bed of a peaceful sleeper. Dr. Jacobs said that in one hour of prime-time television recently, he saw three ads for sleeping pills: two for Lunesta and another for Ambien.

“You’ve got the patient population being bombarded with advertising on TV,” Dr. Jacobs said. “You’ve got increased advertising to physicians. You’ve got a formula for sales going up dramatically.”

One financial analyst, Jon LeCroy of Natexis Bleichroeder, said Lunesta’s ad campaign last fall was tied to the new season of “Desperate Housewives,” whose audience is about 55 percent female. Studies have shown that women have insomnia more frequently than men.

Last week, Sepracor’s stock jumped $8.53 in one day, after Sepracor reported a profit and remarkably strong use of Lunesta in its first year on the market, with sales of $329 million. More than 213,000 doctors wrote 3.3 million prescriptions for it last year, the company says.

Sepracor announced the addition of 450 people to its current sales force of 1,500 to increase marketing of the drug to physicians.

Sanofi-Aventis, with a sales force of 3,000, is working to shift patients from Ambien, which loses its patent protection in October, to the newer version, Ambien CR. The newer pill has a quickly dissolving outer layer meant to immediately induce sleep, with a slower-dissolving inner layer to sustain sleep.

Another drug in the class is Sonata, marketed by King Pharmaceuticals. Because it is short acting, Sonata is recommended for people who have trouble falling asleep but no trouble staying asleep.

Drugs in the class are frequently referred to as “Z” drugs, a play on both their effect and the Z’s in their generic names, like zolpidem (Ambien) and eszopiclone (Lunesta). All aim at a brain neurotransmitter that is believed to reduce neural activity.

Another new entrant to the market, Rozerem, by the Japanese company Takeda Pharmaceuticals, has been available in drugstores since
The Risks of Sleeping Pills

September but has not yet been heavily advertised. The drug works by a different mechanism from the others, acting on the brain’s melatonin receptors, which are believed to play a role in sleep-wake cycles.

Mr. LeCroy, the analyst, who is also a medical doctor, predicts the advertising will intensify if Neurocrine Biosciences and its partner Pfizer are permitted to introduce their new sleeping pill, Indiplon; an F.D.A. decision on that is expected in May.

“That’s going to make the competition get more cutthroat,” Mr. LeCroy said, predicting that the market for branded sleeping pills, currently about $2 billion a year, could grow to $3.8 billion, even with Ambien set to go generic. “This is only going to get crazier.”

The Carlat Psychiatry Report, a newsletter by Dr. Daniel J. Carlat, a psychiatrist in Newburyport, Mass., reviewed the Z drugs recently and concluded that their differences were merely subtle. But Dr. Carlat warned that Lunesta, because it was longer acting, was more likely to cause next-day sleepiness problems “in comparison with some of its cousins.”

Dr. Carlat cited a 1998 study in Britain, published in The Lancet, which found that taking zopiclone, the compound known as the “mother” of Lunesta and marketed in Europe, was linked to an increased risk of automobile accidents.

But Sepracor’s chief financial officer, David P. Southwell, said that Lunesta, while a chemical variant of zopiclone, was a totally different drug. He referred a reporter to the F.D.A.-approved label, which lists clinical studies of next-day effects showing there was no consistent pattern of impaired mental functioning the day after Lunesta use.

The possible role of Ambien was investigated in connection with well-chronicled transportation disasters in 2003 — the crash of the Staten Island Ferry, which killed 11 passengers, and an accident involving a Texas church bus in Tallulah, La., which killed 8 passengers. The assistant captain who was piloting the ferry, like the bus driver, had a prescription for Ambien, but there was no evidence either had taken it before the crashes.

Dr. David G. Fassler, a clinical professor of psychiatry at the University of Vermont College of Medicine, said he was concerned that the heavy marketing and prescribing of the sleep medications would lead to use in patients who have underlying conditions that are left untreated.
“I’m concerned that difficulty sleeping can be a sign of multiple disorders, including problems with anxiety and depression,” he said, expressing worry that patients who are not thoroughly evaluated might be treated for their insomnia while other problems, like anxiety or decreased appetite, are not addressed.

In clinical trials, the most common side effect of the drugs, however, is that people wake up feeling sleepy the next day.

Dr. Daniel J. Buysse, a University of Pittsburgh psychiatrist who has consulted for the industry on sleeping pills, said they were a rare example of drugs in which the desired effect and the major side effect were the same thing. “One occurs when you want it, and the other occurs when you don’t,” he said.

Another problem associated with using sleeping pills is a condition commonly called traveler’s amnesia, in reference to the frequent use by people who travel across time zones. Such amnesia can occur when people return to daytime activities too quickly after taking the drugs.

The labels carry warnings that the drugs should be used only when people can devote a full night to sleeping. In some cases, however, users have reported that they awakened during the middle of the night in sleepwalking states, but — like Mr. Wells, the lawyer in Buffalo — had no recollection of their activities.

The amnesiac effects of Ambien were a factor in the acquittal last week of a United States Air Force linguist who had been charged with raping a colleague while the two were stationed in Qatar. The woman who said she was the victim, also a linguist, testified that she was not sure whether the incident was a dream because she had taken Ambien, according to the Stars and Stripes report on the military trial, which occurred in Britain.

Dr. Buysse said such bouts of nocturnal uncertainty occur occasionally with various Z drugs.

“There have been some case reports of people who have been sleepwalking only when taking the drug,” Dr. Buysse said. “I think it’s rare, and it’s the kind of thing that no one is going to have a very good estimate of. But if it happens to you, who cares if you’re the only person of many?”
The Risks of Sleeping Pills

March 8, 2006

Some Sleeping Pill Users Range Far Beyond Bed

By STEPHANIE SAUL

With a tendency to stare zombie-like and run into stationary objects, a new species of impaired motorist is hitting the roads: the Ambien driver.

Ambien, the nation’s best-selling prescription sleeping pill, is showing up with regularity as a factor in traffic arrests, sometimes involving drivers who later say they were sleep-driving and have no memory of taking the wheel after taking the drug.

In some state toxicology laboratories Ambien makes the top 10 list of drugs found in impaired drivers. Wisconsin officials identified Ambien in the bloodstreams of 187 arrested drivers from 1999 to 2004.

And as a more people are taking the drug — 26.5 million prescriptions in this country last year — there are signs that Ambien-related driving arrests are on the rise. In Washington State, for example, officials counted 78 impaired-driving arrests in which Ambien was a factor last year, up from 56 in 2004.

Ambien’s maker, Sanofi-Aventis, says the drug’s record after 13 years of use in this country shows it is safe when taken as directed. But a spokeswoman, Melissa Feltmann, wrote in an e-mail message, “We are aware of reports of people driving while sleepwalking, and those reports have been provided to the U.S. Food and Drug Administration as part of our ongoing postmarketing evaluation about the safety of our products.”

A spokeswoman for the F.D.A. said the drug’s current label warnings, which say it should not be used with alcohol and in some cases could cause sleepwalking or hallucinations, were adequate. “People should be aware of that,” said the spokeswoman, Susan Cruzan.

While alcohol and other drugs are sometimes also involved in the Ambien traffic cases, the drivers tend to stand out from other under-the-influence motorists. The behavior can include driving in the wrong direction or slamming into light poles or parked vehicles, as well as seeming oblivious to the arresting officers, according to a presentation last month at a meeting of forensic scientists.
“These cases are just extremely bizarre, with extreme impairment,” said Laura J. Liddicoat, the forensic toxicology supervisor at a state-run lab in Wisconsin who made the presentation.

Her presentation, which reported on six of the cases, was made at a meeting of the American Academy of Forensic Sciences, where her counterparts from other parts of the country swapped similar tales.

Several of Ms. Liddicoat’s cases involved drivers whose blood revealed evidence of Ambien overdoses. In one of them the driver, who was also taking the antidepressant citalopram, crashed into a parked car, was involved in another near collision, then drove over a curb. When confronted by police, he did not recall any of the recent events, according to the presentation.

Ms. Liddicoat did not describe any of those cases as sleep-driving — in fact, she said she had not heard of that defense — and it is possible that some drivers’ claims of driving while asleep may be mere Ambien alibis. But some medical researchers say reports of sleep-driving are plausible.

Doctors affiliated with the University of Minnesota Medical Center who have studied Ambien recently reported the cases of two users who told doctors they sleep-drove to the supermarket while under the drug’s influence. Neither of the patients remembered the episode the next day, according to Dr. Carlos Schenck, an expert in sleep disorders who is the lead researcher in the study.

“Luckily, neither of them got hurt,” said Dr. Schenck, who added that sleep-driving — which really occurs in a twilight state between sleep and wakefulness — was more common than people generally suspect. He said he believed that Ambien was an excellent sleep agent, but that patients need to be better warned about its potential side effects.

The traffic cases around the country include that of Dwayne Cribb, a longtime probation and parole officer in Rock Hill, S.C. Mr. Cribb says he remembers nothing after taking Ambien before bed last Halloween — until he awoke in jail to learn he had left his bed and gone for a drive, smashed into a parked van and driven away before crashing into a tree. Mr. Cribb is still facing charges of leaving the scene of an accident.

A registered nurse who lives outside Denver took Ambien before going to sleep one night in January 2003. Sometime later — she says she remembers none of the episode — she got into her car wearing only a thin nightshirt in 20-degree weather, had a fender bender, urinated in the
middle of an intersection, then became violent with police officers, according to her lawyer.

The woman, whose lawyer says she previously had a pristine traffic record, eventually pleaded guilty to a reduced charge of careless driving after the prosecutors partly accepted her version of events, said the lawyer, Lloyd L. Boyer.

Many states do not currently test for Ambien when making impaired-driving arrests. But a survey still under way by a committee from the forensic sciences group and the Society of Forensic Toxicologists found that among laboratories that conduct tests of drivers’ blood samples for two dozen states, 10 labs list Ambien among the top 10 drugs found in impaired drivers, according to Dr. Sarah Kerrigan, a forensic toxicologist in Houston involved in that survey.

Ms. Liddicoat, in Wisconsin, is among experts who suggest that Ambien may need a stronger warning label. Others arguing that case include doctors, Ambien users and defense lawyers.

“Doctors are handing out these drugs like Pez,” said William C. Head, an Atlanta lawyer who is one of the nation’s leading defense lawyers specializing in impaired-driving cases.

The F.D.A., which would have to order any labeling changes, says it is not aware of any pattern of problems with the drug. Still Ms. Cruzan, in response to a reporter’s question, said the agency would look into unusual sleepwalking episodes.

Including the notifications from Sanofi, which as a matter of policy the F.D.A. declined to discuss, the agency did receive 48 “adverse event” reports in 2004 involving Ambien use without other drugs. They involved three cases of sleepwalking, six reports of hallucinations and one traffic accident.

Ambien’s competitors — Lunesta by Sepracor and Sonata by King Pharmaceuticals — are not as widely used in this country, and do not seem to be cropping up with any frequency on police blotters. Ambien sales last year reached $2.2 billion, according to IMS Health. Among the three drugs, Ambien accounted for 84 percent of prescriptions dispensed.

A federal prosecutor was persuaded that Ambien played a part in a well-publicized case last summer involving not a car but an airliner. A US Airways flight from Charlotte, N.C., to London last July was diverted to
The man, Sean Joyce, a British painting contractor, became agitated, tore off his shirt and threatened to kill himself and fellow passengers, according to court documents. If convicted, Mr. Joyce could have faced a maximum sentence of 20 years in jail for interfering with a flight crew, according to his lawyer, Michael C. Andrews.

But under a plea agreement Mr. Joyce was sentenced to five days already served, after the prosecutor accepted his story that his eruption, which he said he could not recall at all, occurred as a result of taking one Ambien pill and drinking two individual-serving bottles of wine.

Many of the impaired-driving cases involve people who drank alcohol before taking Ambien. Mr. Cribb, for instance, said he had two beers with dinner before he took the drug and went to bed.

Sanofi-Aventis says that while sleepwalking may occur while taking Ambien, the drug may not be the cause. It also notes that the warnings with Ambien, including those in its television ads, specifically instruct patients not to use it with alcohol and to take it right before bed.

Alcohol has sometimes been shown to cause sleepwalking, and it can also magnify Ambien’s effects, according to Dr. Mark Mahowald, director of the Minnesota Regional Sleep Disorders Center at Hennepin County Medical Center, who is also involved in Dr. Schenck’s study.

In the past, the center has received grant funding from Sepracor, Lunesta’s maker, but Dr. Mahowald said that none of the researchers currently received any funding from sleeping pill companies.

Ambien’s alcohol warning is apparently ignored by many people. But Mr. Head, the defense lawyer, says he has concluded that no one should take Ambien the same evening they have been drinking alcohol. “Not even a toast,” he said.

Mr. Head is now defending a man in Decatur, Ga., who, after having three drinks one night, said he took two Ambien and was in bed watching David Letterman’s monologue on television. Without realizing it, the man says, he got back out of bed and behind the wheel and was arrested on multiple charges that included driving on the wrong side of the road.
Too many other people taking Ambien also evidently disregard the other label guidelines.

Ann Marie Gordon, manager of Washington State’s toxicology lab, said that many of those arrested reported that they took Ambien while driving so it would “kick in” by the time they got home. “Hello — it kicked in before you got home?” Ms. Gordon said. “That’s not a good thing. I’m amazed at the number of people who do that.”

But misuse of the drug may not explain all the cases. The nurse near Denver took a single Ambien and went to bed, according to her lawyer, Mr. Boyer of Englewood, Colo. Mr. Boyer said that only when the woman returned home after her arrest did she discover a partly consumed bottle of wine on her counter — unopened when she went to bed, she said — leading her to suspect she had begun drinking after taking Ambien.

Research by Dr. Schenck and others elsewhere have found evidence that Ambien users engaged, unawares, in various middle-of-the-night behaviors. In a study published in 2001, researchers at the Mayo Clinic Sleep Disorders Center reported on five cases of unusual nighttime eating, sometimes while sleepwalking, in patients taking Ambien. The chief of physical medicine and rehabilitation for the VA North Texas Health System in Dallas, Dr. Weibin Yang, said he became aware of Ambien’s potential side effects while at another hospital treating a 55-year-old patient after hip surgery.

The man, who had no history of sleepwalking, walked into a hospital corridor one night, where he urinated on the floor. On another night, he got out of bed and told nurses he was going to church. Dr. Yang said the patient was also taking other medications, but the sleepwalking stopped when Ambien was discontinued. The patient, he said, had no recollection of either event.

Dr. Yang said such experiences persuaded him that people could drive, without realizing it, after taking Ambien.

Meanwhile in South Carolina, Mr. Cribb, who has already pleaded guilty to driving under the influence, still faces a charge of leaving the scene of an accident. He says he has sworn off Ambien. “There has to be a stronger warning,” he said, “about what this drug does to you.”

Ron Nixon contributed reporting for this article.
NEEDS FOR HYPNOTICS RESEARCH

Today, nobody can be certain that any of the prescription sleeping pills is safe for long-term use or even that they help sleep with long-term use. Although the potential risk of intermittent use (a few times a month) seems to be less than the risk of nightly use, our CPSI and CPSII studies indicated that sleeping pills may be unsafe in any amount. It is important to recognize that both studies were done before some of the drugs popular today came on the market. In particular, zolpidem and zaleplon (the most popular U.S. sleeping pills as we begin the 21st century) were not tested. Different experts may have different opinions about the likelihood of long-term safety, but the fact is that nobody knows for sure about particular drugs. The only way to assure public safety is to do long-term randomizing trials.

It is not a unique idea that long-term studies should be done. The National Institutes of Health (NIH) are doing long-term studies of diet and exercise, hormone replacement and vitamins, cholesterol-lowering drugs and aspirin. Of the psychoactive drugs, long-term studies have been supported for anti-depressant and anti-psychotic drugs, mood stabilizers (such as lithium), tranquilizers, narcotic agonists and antagonists, and stimulants for treatment of hyperactive kids. Truthfully, hypnotics are the only class of psychotropic drugs for which long-term studies have not been supported by the NIH. In a 1997 search of the CRISP list of NIH-supported projects, I found about 140 clinical studies of other psychotropic drugs, but none on sleeping pills. This is neglectful, considering the proportion of total psychotropic drug sales which the sleeping pill market occupies.

Although I receive generous grant funding in other areas of sleep research, the federal agencies have never been willing to support any studies of sleeping pills which I have proposed. I do not take it personally, since I know other investigators have the same problem. There is a mind set against funding studies of sleeping pills and a lot of passing the buck among different NIH Institutes. You could count on one hand (and have fingers left) the total number of clinical trials of hypnotic drugs funded by NIH in its entire half-century history.

Lack of government curiosity about sleeping pill prescribing is exceptional. As mentioned above, government agencies denied that they had data on overall U.S. consumption of sleeping pills. They are certainly more careful in studying other addicting drugs.

The drug companies have been happy restricting their studies to short-term trials and avoiding studies which might show lack of long-term
benefit, knowing full well that the majority of their sales go to the chronic users. It is unreasonable to expect these companies to voluntarily do studies which might bring bad news, decreasing their sales and resulting in huge potential litigation. The reasonable choices are for private foundations to fund the studies, or more likely, for the federal government to assume its responsibility.

Before I denounce the drug companies excessively, let me mention that the same heavy prescribing of hypnotics existed in Communist countries before the dissolution of the Soviet block, and there was a similar lack of studies behind the Iron Curtain. One should not ascribe the scientific neglect of sleeping pills entirely to the profit motive.

The cost of studies which would establish the long-term benefits/risks ratios of the most popular hypnotics would probably be $10-20 million for a period of several years. This would mean devoting only 1-2% of sleeping pill costs for long-term research, in a sleeping-pill-giving industry which grosses far over a billion dollars a year. The retail costs of the hypnotics drugs themselves may surpass a billion, and in addition, the fees of the prescribing doctors, the necessary laboratory tests, etc. amplify the total cost. Compare this with other areas of drug research, where the research costs may reach 25% of sales, or aircraft, computer and defense industries, where the R&D costs may reach 50% of total costs.

The Congress would have several choices for how to finance this research. It could require the manufacturers by law to perform the needed research. It could impose a user-fee on hypnotics (either at the retail level or the manufacturer level) to do the studies. A cost of a nickel a pill added to pills which cost $1.50 each would be a trivial cost to the consumer and well worth while in keeping consumers safe. To the extent that this small cost might discourage people from using sleeping pills, it would be doing them a favor. Such a user-fee might be regarded like the levies on other addicting substances such as cigarettes and alcohol. Congress could take the money out of the overall appropriations for health services research or for the National Institutes of Health, or it could conceivably appropriate new funds from general revenues. It is for the Congress to decide from where the money should come, but one way or another, the studies should be done.

Sleep Drugs Found Only Mildly Effective, but Wildly Popular

By STEPHANIE SAUL

Your dreams miss you.

Or so says a television commercial for Rozerem, the sleeping pill. In the commercial, the dreams involve Abraham Lincoln, a beaver and a deep-sea diver.

Not the stuff most dreams are made of. But if the unusual pitch makes you want to try Rozerem, consider that it costs about $3.50 a pill; gets you to sleep 7 to 16 minutes faster than a placebo, or fake pill; and increases total sleep time 11 to 19 minutes, according to an analysis last year.

If those numbers send you out to buy another brand, consider this, as well: Sleeping pills in general do not greatly improve sleep for the average person.

American consumers spend $4.5 billion a year for sleep medications. Their popularity may lie in a mystery that confounds researchers. Many people who take them think they work far better than laboratory measurements show they do.

An analysis of sleeping pill studies found that when people were monitored in the lab, newer drugs like Ambien, Lunesta and Sonata worked better than fake pills. But the results were not overwhelming, said the analysis, which was published this year and financed by the National Institutes of Health.
The Risks of Sleeping Pills

The analysis said that viewed as a group, the pills reduced the average time to go to sleep 12.8 minutes compared with fake pills, and increased total sleep time 11.4 minutes. The drug makers point to individual studies with better results.

Subjects who took older drugs like Halcion and Restoril fell asleep 10 minutes faster and slept 32 minutes longer than the placebo group. Paradoxically, when subjects were asked how well they slept, they reported better results, 52 extra minutes of sleep with the older drugs and 32 minutes with the newer drugs.

“People seem to be getting a lot of relief from sleeping pills, but does getting 25 minutes of sleep really give you all that relief?” asked Dr. Wallace B. Mendelson, the former director of a sleep disorders unit at the University of Chicago. “A bigger aspect of this is that they change a person’s perception of their state of consciousness.”

Dr. Mendelson is semiretired and is a consultant for pharmaceutical companies.

Dr. Karl Doghramji, a sleep expert at Thomas Jefferson University in Philadelphia, agreed. “Sleeping pills do not increase sleep time dramatically, nor do they decrease wake time dramatically,” he said. “Despite those facts, we do find patients who, when they take them, have a high level of satisfaction.” Dr. Doghramji has disclosed in the past that he is a consultant to pharmaceutical companies.

Most sleeping pills work on the same brain receptors as drugs to treat anxiety. By reducing anxiety, the pills may make people worry less about not going to sleep. So they feel better.

Another theory about the discrepancy between measured sleep and perceived sleep involves a condition called anterograde amnesia. While under the influence of most sleep medications, people have trouble forming memories. When they wake up, they may simply forget they had trouble sleeping.

“If you forget how long you lay in bed tossing and turning, in some ways that’s just as good as sleeping,” said Dr. Gary S. Richardson, a sleep disorders specialist at Henry Ford Hospital in Detroit who is a consultant and speaker for pharmaceutical companies and has conducted industry-sponsored research.

Sleep, after all, causes a natural state similar to amnesia, one reason toddlers often forget their violent nightmares by the next morning. If you stay in bed, as most people taking sleeping pills do, amnesia is not a bad thing.
Even some people who sleepwalked while taking Ambien, which was implicated in cases of odd, sometimes dangerous behavior while sleeping, believed they were having a good night’s sleep. Rosemary Eckley, a graphic artist in New London, Wis., said she thought she was sleeping well on Ambien but woke to find her wrist broken, apparently in a fall while sleepwalking, she wrote in an e-mail exchange.

Reports of sleep-eating and sleep-driving on Ambien are reminiscent of problems nearly 20 years ago with Halcion. Some people who took that drug to sleep on airplanes developed a condition known as traveler’s amnesia. They landed at their destinations, then got lost or forgot where they were, prompting the authorities in several countries to withdraw Halcion from the market.

Reports show that Ambien and similar drugs, advertised as safer than benzodiazepines like Halcion, can cause similar problems. The reports prompted the Food and Drug Administration to ask manufacturers to develop warning guides for distribution with virtually all sleep drugs. Despite such problems, most specialists say sleeping pills are generally safe. Dr. Mark W. Mahowald, director of the Minnesota Regional Sleep Disorders Center, which is involved in documenting cases of sleep-eating under the influence of Ambien, said serious side effects were rare and should not discourage the use of the pills.

The class of drugs known as nonbenzodiazepines, sometimes called “Z” drugs, includes Ambien, Lunesta and Sonata. Ambien and its generic equivalent, zolpidem, are the most widely used, together accounting for 40 percent of the market.

Newer drugs like Lunesta and Ambien CR, a controlled-release formula, cost about $4 a pill. Zolpidem recently sold for $2 a pill on walgreens.com.

Of the three drugs in the class, Sonata, which also retails for about $3.50 a pill, remains in the body the shortest time and, therefore, is normally used by people who have trouble falling asleep but no problem staying asleep. The advocacy organization Public Citizen’s Health Research Group says its benefits are so minimal it should not be used.

King Pharmaceuticals, the maker of Sonata, did not respond to several messages seeking comment.

A study by an Oregon State University group that reviews the safety and effectiveness of drugs found that Lunesta offered little benefit over generic Ambien or older benzodiazepines, but cost more. Jonae Barnes, a spokeswoman for Lunesta’s maker, Sepracor, said the company strongly
disagreed and added that the Oregon group did not adequately consider waking time after falling asleep, an area in which Lunesta performed better.

Users also sometimes report that Lunesta leaves a bad taste in their mouths, according to studies of the drug.

Dr. Mahowald said the older drugs, including Halcion, also known as triazolam, offered better value than the newer ones.

“We tend to use the old benzodiazepines,” he said of his practice. “They appear to be as effective as some of the newer ones, and they’re infinitely less expensive.” Dr. Mahowald said that his center participated in industry-sponsored clinical research, but that he did not personally work as a consultant or adviser to pharmaceutical companies.

Such drugs, which include flurazepam, brand name Dalmane, and temazepam, Restoril, sell in generic versions for 30 to 50 cents each.

Another inexpensive alternative, and one of the most widely used sleep medications in this country, is the antidepressant trazodone. It works well in many patients, but some people say it leaves them groggy the next day, according to Dr. Daniel Carlat, a psychiatrist in Newburyport, Mass., who publishes The Carlat Psychiatry Report and declines industry financing. In men, trazodone has been linked to rare cases of priapism, prolonged and painful erections.

Some patients who fear using sleeping pills turn to over-the-counter remedies like Tylenol PM and Advil PM. Those contain the painkillers acetaminophen and ibuprofen combined with an antihistamine, diphenhydramine, the ingredient in the allergy medication Benadryl.

Antihistamines are known to make people sleepy, but there is little evidence that they improve sleep. They can also cause next-day sedation that impairs driving, as well as racing heartbeat and constipation. The Medical Letter, which reviews drugs, recommends against using antihistamines for sleep. Some doctors say users of Tylenol PM may be taking acetaminophen they do not need. Acetaminophen overdoses can cause liver failure.

Rozerem, with its unusual advertising campaign, has at least one benefit over other medications. Because it works by a different mechanism from the others, it is not a controlled substance and apparently does not affect the ability to form memories. It may be the sleeping pill of choice for
elderly people who have trouble falling asleep, but suffer memory problems.

Still, researchers and drug companies have yet to find a holy grail. “The problem is, there is no ideal hypnotic,” said Dr. Manisha Witmans, a sleep medicine specialist at the University of Alberta’s Evidence-Based Practice Center. “The magic pill for sleep has not been invented yet.”

Curing Insomnia Without the Pills
Dreaming of better sleep?

(Rahav Segev/The New York Times)

Better sleep doesn’t have to come in a pill.

For people with chronic insomnia, studies show that simple behavioral and psychological treatments work just as well, and sometimes better, than popular medications, according to a report in The Journal of Family Practice.
The Risks of Sleeping Pills

The medical journal *Sleep* last year reported on five high-quality trials that showed cognitive behavioral therapy helped people suffering from insomnia fall asleep sooner and stay asleep longer. Another *American Journal of Psychiatry* analysis of 21 studies showed that behavioral treatment helped people fall asleep nearly nine minutes sooner than sleep drugs. In other measures, sleep therapy worked just as well as drugs, but without any side effects.

The behavioral strategies for better sleep are deceptively simple, and that’s one reason why many people don’t believe they can make a difference. One of the most effective methods is stimulus control. This means not watching television, eating or reading in bed. Don’t go to bed until you are sleepy. Get up at the same time every day, and don’t nap during the day. If you are unable to sleep, get out of bed after 15 minutes and do something relaxing, but avoid stimulating activity and thoughts.

So-called sleep hygiene is also part of sleep therapy. This includes regular exercise, adding light-proof blinds to your bedroom to keep it dark and making sure the bed and room temperatures are comfortable. Eat regular meals, don’t go to bed hungry and limit beverages, particularly alcohol and caffeinated drinks, around bedtime.

Finally, don’t try too hard to fall asleep, and turn the clock around so you can’t see it. Watching time pass is one of the worst things to do when you’re trying to fall asleep.

It may be hard to believe, but studies show these simple steps really do make a meaningful difference for people with sleep problems. These interventions are based on the notion that thoughts and behaviors can “hyper-arouse” the central nervous system and deregulate sleep cycles, resulting in chronic insomnia, reports Family Practice.

If these steps don’t work, talk to your doctor about a referral to a sleep therapist, who can also teach you additional relaxation techniques to help bring on sleep. Sometimes, a therapist might work with you to reset your sleep-wake schedule, a more involved process whereby patients adjust their bedtime each night over the course of a few weeks.
